INTRODUCTION
The increasing incidence of cirrhosis in the UK has driven the rise in such patients requiring non-hepatic surgery as an emergency (eg, irreducible umbilical hernia) or electively (eg, cardiac or colon cancer surgery). There has been a long-standing reticence to operate on such patients due to their perceived poor outcomes, which has potentially disadvantaged this patient group.

Surgical outcomes vary considerably according to the type of surgery, type of anaesthesia and importantly the stage of liver disease, with clinically significant portal hypertension (CSPH) defined as a hepatic venous pressure gradient (HVPG) ≥10 mm Hg heralding the development of varices, and further progression to decompensation. Additionally, comorbidities such as obesity, diabetes and cardiovascular disease present further anaesthetic and surgical challenges for the growing cohort of patients with non-alcoholic fatty liver disease-related cirrhosis.

The assessment of surgical risk in patients with cirrhosis is increasingly important but limited by a lack of prospective controlled data and significant heterogeneity in risk assessment pathways. Although AGA guidance on this topic has been published, there is no clear guidance in the UK. This position statement aims to summarise the current evidence and advise members of BSG and BASL on the current options for presurgical assessment and future directions. This guidance document has been reviewed by the BASL Portal Hypertension Special Interest Group Steering Committee, BSG Liver Section, and BSG Clinical Services and Standards Committee.
Guideline

Guidance statements
1. Patients with cirrhosis are considered high-risk candidates for non-hepatic surgery, in particular intra-abdominal and cardiothoracic procedures. The risk is highest in Child-Turcotte-Pugh (CTP)-B and C disease and correlates with the degree of portal hypertension.
2. The preoperative assessment of patients with cirrhosis being considered for non-hepatic surgery is complex and a case-by-case decision is advised.
3. Multidisciplinary assessment including hepatology, anaesthetics and surgery is advised, with involvement of other disciplines (e.g., radiology, haematology or nutrition/physiotherapy) where appropriate.
4. In eligible patients, particularly those with decompensated cirrhosis, consideration should be given to deferring elective surgery until after liver transplantation where applicable. Where liver transplantation is not an option in decompensated cirrhosis, referral to palliative care services should be considered unless aetiology of cirrhosis is modifiable for example, alcohol abstinence, antiviral therapy.
5. The current bespoke prognostic scoring systems such as Mayo Risk Score, VOCAL-Penn and Adequate Operative Treatment for Liver Cirrhosis (ADOPT-LC) can be considered to aid multidisciplinary team decisions, in addition to CTP and Model for End-stage Liver Disease (MELD) score.
6. Measuring HVPG can provide additional information and may be considered as an adjunct to other prognostic parameters where available.
7. In compensated cirrhosis, transjugular intrahepatic portosystemic shunting (TIPSS) prior to surgery can be considered in those at high risk as quantified by the presence of varices, prognostics scoring systems and/or HVPG. However, further comparative multicentre studies are urgently needed, to guide selection of patient most likely to benefit.
8. Algorithm for assessment of patients with cirrhosis undergoing elective surgery is presented in figure 1.

Pre-surgery assessment
Presurgery evaluation requires that we consider specific harms that may either complicate surgery or recovery from surgery. These risks should be assessed and explained to the patient, with appropriate steps put in place to mitigate where possible.

History, physical examination and blood tests may reveal findings suggestive of chronic liver disease. There should be a low threshold to consider further investigations such as imaging and liver stiffness measurement where there is clinical suspicion of liver disease since patients with compensated advanced chronic liver disease can present with normal liver function tests and absence of overt clinical stigmata of chronic liver disease. A multidisciplinary assessment is strongly advised with input from hepatology, anaesthetics, surgery and other disciplines where appropriate such as radiology, haematology, nutrition and physiotherapy. The risks include: (1) general anaesthesia which could be mitigated by the use of regional techniques; (2) ...

Figure 1  Algorithm for assessment of patients with cirrhosis undergoing elective surgery. *HVPG measurement is preferable where available. **LSM applicable only in compensated cirrhosis. ***High-risk surgery includes cardiovascular, thoracic and open abdominal surgery. ****Low-risk surgery comprises of minimally invasive, abdominal wall and orthopaedic surgery. ** Includes addressing individual risk factors such as alcohol intake, increased BMI, measures to improve ASA status and portal decompression, for example, TIPSS in suitable patients. *****Only available in selected centres. ASA, American society of Anesthesiology score; BMI, body mass index; CSPH, clinically significant portal hypertension; CTP, Child-Turcotte-Pugh score; HVPG, hepatic venous pressure gradient; LSM; liver stiffness measurement; MDT, multidisciplinary team discussion; MELD, Model for End-Stage Liver Disease; OGD, oesophagogastroduodenoscopy; TIPSS, transjugular intrahepatic portosystemic shunting.

implied bleeding risk using traditional indices such as international normalised ratio (INR), activated partial thromboplastin time (APTT) and platelet count, which in this population do not reflect deranged haemostatic mechanisms, making an assessment of bleeding risk challenging; (3) infection which can precipitate decompensation; (4) compromised nutritional status with malnutrition and sarcopenia hampering postoperative recovery and wound healing; (5) acute kidney injury precipitated by hypovolaemia due to depleted albumin, contrast agents, infection or anaesthesia; (6) cardiovascular compromise due to stress of surgery unmasking undiagnosed cardiomyopathy. Decompensated cirrhosis (defined by ascites, encephalopathy, variceal bleeding, and/or jaundice) results in a much higher risk of poor outcomes, with increased propensity to precipitate acute on chronic liver failure post-surgery. In this group, an individualised decision on whether surgery can be deferred until after liver transplantation for eligible candidates should be considered. Decompensated patients with non-hepatic malignancy can be particularly challenging since pre-emptive liver transplantation is normally contraindicated. Elective surgery is absolutely contraindicated in acute liver failure, acute viral or alcoholic hepatitis and American Society of Anesthesiologists (ASA) Physical Status class V. Intra-abdominal or cardiothoracic surgical procedures are considered higher risk—the former due to the potential presence of portal hypertension, and the latter due to the adverse impact of reduced cardiac output in patients who are already vasodilated, with low blood pressure and reliant on their compensatory high cardiac output state.

**Specific prognostic models**

Most studies of prognostic models are observational or retrospective and limited by significant heterogeneity with regard to the type of surgery, severity of liver disease and whether surgery was elective or emergency. Traditional prognostic scoring systems including CTP and MELD, have an established role but can overestimate surgical risk. Bespoke prognostic models have also been proposed which can provide a greater precision (table 1). These include the Mayo Risk Score, VOCAL-Penn and ADOPT-LC score (table 1). These are all based on retrospective data, some dating back 25 years, and do not quantify the degree of portal hypertension. A recent multicentre prospective study found that ASA class (HR III vs II = 2.98 (95% CI 0.7 to 13.2), HR IV vs II = 9.97 (95% CI 2.0 to 50.4), p = 0.008), high-risk surgery (HR = 3.65 (95% CI 1.4 to 9.3), p = 0.006) and HVPG (HR = 1.14 (95% CI 1.05 to 1.25), p = 0.003) were strongly predictive of 1 year mortality (C-statistic > 0.8). HVPG is invasive and not widely available, but given that values > 16 mm Hg (and especially ≥ 20 mm Hg (HR = 5.67 (95% CI 2.4 to 13.2))) are independently associated with high risk of 1-year postsurgical mortality, its use, particularly in patients with compensated cirrhosis or with previous decompensation, may be considered where available.

**Risk associated with different types of non-hepatic surgery**

Patients with liver disease have high morbidity and mortality across the spectrum of surgical procedures. Operative risk is dependent on severity of liver disease, type and mode of surgical procedure, concomitant medical conditions, nutritional and performance status of the individual, and peri- and postoperative expertise. Studies on the outcome of patients undergoing surgery are highly variable with the majority of studies being retrospective and single-centre, and lacking detail of liver disease and appropriate quality controls. A systematic review by de Goede et al quotes general surgical risk for 30-day mortality and morbidity to be 11.6% and 30.1%, respectively. Presence of portal hypertension further heightens the mortality with colectomy, abdominal aortic aneurysm repair or coronary artery bypass grafting (CABG) having a 12.3-fold, 14.3-fold, 7.8-fold and 22.7-fold higher risk, respectively, when compared with patients without cirrhosis.

**Laparoscopic versus open surgery**

Laparoscopic surgery was deemed a relative contraindication in cirrhosis due to risk of rupturing abdominal varices but multiple studies have demonstrated favourable outcomes following this approach. It’s safety in CTP-C patients is not yet proven, hence surgery in such patients may be limited to conservative measures. In the context of cirrhosis, laparoscopic cholecystectomy has been the most common procedure assessed. In a meta-analysis of randomised controlled trials comparing laparoscopic and open cholecystectomy (n = 234 patients (97% CTP-A or B)), there were no postoperative deaths and the laparoscopic approach was associated with fewer postoperative complications (p = 0.03), shorter hospital stay (p < 0.001) and quicker resumption of normal diet (p < 0.001). Laparoscopic inguinal hernia repair can be performed safely and there are also favourable outcomes when comparing laparoscopic to open appendectomy.

coagulopathy. Ascites heightens the risk of wound complications such as dehiscence. A meta-analysis demonstrated that, compared with a non-cirrhotic group, patients with cirrhosis who underwent primary colorectal cancer surgery had more major complications, a higher reoperation rate and increased short-term mortality. (table 2). Additional risk factors for mortality included older age, elevated bilirubin, prolonged prothrombin time, higher CTP class, MELD score >15, intraoperative transfusions and comorbidities (cardiovascular disease, chronic kidney disease, paraplegia and malnutrition). Nonetheless, improvements in surgical technique and perioperative care have led to reduced mortality rates over the last two decades. Mortality was reported to be 13% in a study of 72 cirrhosis patients undergoing colorectal surgery in 2003. However, in a more recent study, Lee et al reported mortality of 3.1% 161 patients undergoing colorectal surgery. Hernia repairs

The incidence of abdominal wall hernia in patients with cirrhosis is 16%, which rises to 24% in patients with ascites. Half of these are umbilical hernias and 60% of patients experience recurrence following repair. Mortality is quoted to be 6% for umbilical hernia repair, which is higher in the emergency setting. However, a randomised controlled trial concluded that elective repair of an umbilical hernia is safe in cirrhosis patients, even in patients with a relatively high MELD score (table 2). The presence of ascites appears to be strongly predictive of hernia recurrence.

Cardiovascular surgery

Morbidity and mortality in patients with cirrhosis undergoing cardiovascular surgery is increased with higher risk of infectious, respiratory and renal complications alongside longer hospital stay. CABG and valvular surgery carry approximately fivefold

| Agarwal et al. 2021 | Systematic review and meta-analysis including 18 studies and 471 patients with obesity and liver cirrhosis undergoing bariatric surgery (mainly LSG and PGB) | ► 397/423 patients with defined CTP class were CTP-A  
► The weighted pooled proportion of overall complications was 22.14% and all-cause 90-day mortality was 0%  
► Significant increase in postoperative complications (p=0.001) but no difference in all-cause 90-day mortality (p=0.1165) compared with controls. | |
| Appendectomy Rashid et al. 2022 | Meta-analysis of 923 patients with cirrhosis undergoing appendectomy | ► 30-day mortality 9% vs 0.3% in cirrhosis and non-cirrhosis patients, respectively.  
► Laparoscopic appendectomy appeared safer with a mortality of 0.5% in comparison to open appendectomy with mortality of 3.2% | |
| Umbilical hernia Snitijar et al. 2022 | Systematic review of 13 prospective, 10 retrospective studies including 3229 patients | ► Evidence was graded as very low quality for all outcomes.  
► Mortality quoted to be 6% (n=191).  
► Patients with cirrhosis are eight times more likely to die after surgery compared with patients without cirrhosis. | |
| De Goede et al. 2021 | Randomised controlled trial (CRUCIAL trial) with 2 years of follow-up recruiting 34 patients with umbilical hernia in liver cirrhosis and ascites | ► Randomised controlled trial (16—elective repair; 18—conservative management)  
► After 24 months, 8 (50%) assigned to elective repair, in comparison to 14 (77.8%) assigned to conservative treatment had no significant difference in morbidity. | |
| Grey et al. 2008 | Retropective analysis of 1421 cases, 127 (8.9%) cirrhotics | ► Elective repair in cirrhosis is associated with similar outcomes in patients without cirrhosis.  
► Cirrhotic patients were more likely to undergo emergency repair (26% vs 4.8%; p<0.001), concomitant bowel resection (8.8% vs 0.8%; p=0.001), return to theatre (7.9% vs 2.5%; p=0.006) and increased length of stay (4 vs 2 days; p=0.01) | |
| Eker et al. 2011 | Prospective study | ► In total, 30 patients (6 CTP-A, 19 CTP-B and 5 CTP-C) with a median MELD score was 12 (IQR 8–16).  
► Elective umbilical hernia repair are safe with no post-operative intensive care admissions and only 2 of 30 patients died; neither of deaths were attributable to umbilical hernia repair. | |
| Carbonell et al. 2005 | Nationwide retrospective cohort study 32,033 patients (30,836 non-cirrhotic and 1197 cirrhotics) | ► Cirrhotics had a higher age distribution (p=0.001) underwent ICU admission more commonly (15.9% vs 6%; p<0.001), had a longer length of stay (5.4 vs 3.7 days), and higher mortality (16.5% vs 13.8%; p<0.008), and mortality (2.5% vs 0.2%; p<0.001) compared with non-cirrhotics.  
► Mortality was seven-fold higher in patients undergoing emergency repair (3.8% vs 0.5%; p<0.001) | |
| Marsman et al. 2007 | Retropective study between 1990 and 2004 34 cirrhosis patients | ► Elective hernia repair was successful in 12 out of 17 patients without complications and recurrence. 3/17 wound related problems and 4/17 had recurrence.  
► Conservative management was only successful in 23%; 10/13 attended hospitals for incarceration of which 6 required emergency hernia repairs. Two patients managed conservatively died from complications of umbilical hernia. | |
| Pinheiro et al. 2020 | Prospective cohort study 246 patients with cirrhosis | ► A total of 246 patients (57 underwent elective hernia repair and 189 who opted for ‘wait and see’ approach) were included in the study. Of the latter, 43 (22.7%) patients required emergency hernia repair due to complications such as ascites leakage due to skin rupture in hernia site (n=28), incarceration (n=7), small bowel strangulation (n=3), and extensive skin necrosis or ulceration (n=3).  
► MELD score >11 (HR 8.0; p=0.011) and emergency hernia repair (HR 5.35; p=0.005) were identified as risk factors for 30-day mortality. | |
| Inguinal hernia Oh et al. 2011 | Retropective study over 10-year period 780 patients having inguinal hernia repair. 129 patients with cirrhosis | ► Morbidity (9.1–16.7%) is not significantly higher than patients without cirrhosis  
► Overall mortality ranging from <1% to 2.7%  
► Cumulative recurrence rates were not significantly different between cirrhosis and non-cirrhosis group (p=0.87) | |
| Pati et al. 2008 | Prospective evaluation of QOL by questionnaire including 32 patients. | ► Inguinal hernioplasty in patients with cirrhosis is a safe procedure and improves quality of life. | |
| Cardiovascular Chou et al. 2017 | Nationwide, population-based study from Taiwan between 1997 and 2001 including 1030 Liver patients and 1948 matched controls without cirrhosis. | ► 1 year survival was 68 vs 81% (p<0.001) in cirrhosis for CABG and valve surgery | |
| Hayashida et al. 2004 | Retropective study between 1989 and 2003 of 18 patients with cirrhosis undergoing cardiac operations | ► Overall postoperative mortality—17%  
► CTP-A—no increased mortality when undergoing elective cardiac surgery  
► CTP-B and C—mortality rate 50%–100% after cardiopulmonary bypass | |
| Jacob et al. 2015 | Systematic review (19 studies) of short-term and overall mortality in patients with liver cirrhosis classified by CTP score undergoing cardiac surgery. | ► CTP score reporting 30-day mortality noted to be 9%, 37% and 52% for CTP class A, B and C, respectively.  
► One-year mortality was reported to be 27.2%, 66.2% and 78.9%, respectively, for CTP class A, B and C, respectively. | |
| Araujo et al. 2017 | Retropective, propensity-matched, case-control study of 1197 patients with liver dysfunction undergoing cardiac surgery (n=755CABG, n=442 valve surgery) | ► Increased mortality was observed for both CABG (OR 5.19, p=0.0001) and valve surgery (OR 7.49, p<0.001) in comparison to controls.  
► Higher rates of complications (bleeding, respiratory, renal, infections) in patients with liver dysfunction and CABG. | |

Continued
and sevenfold increased risk of mortality in cirrhosis, respectively. A meta-analysis (CABG, valvular surgery and cardiopulmonary bypass) quoted 1-year mortality at 20.6%, 43.6% and 56.5% for patients with CTP A, B and C, respectively. Both CTP and MELD score reliably predict mortality, and cardiopulmonary bypass is not recommended in patients with an MELD >13.5 or CTP ≥8. Despite these data, cardiac surgery risk prediction models do not consider liver dysfunction as a surgical risk factor. Surgical aortic valve replacement carries higher mortality in comparison to transcatheter aortic valve replacement (TAVR), therefore, TAVR is recommended in cirrhotic patients. There are limited data on abdominal aortic aneurysm repair but CTP-B and MELD ≥10 are associated with reduced survival.

### Upper gastrointestinal and bariatric surgery

Upper gastrointestinal surgery outcomes in patients with cirrhosis are variable. Emergency surgery for complicated peptic ulcer disease (perforation and bleeding) is associated with a high mortality rate (23%–64%). For gastric cancer operations, morbidity and mortality in cirrhosis patients is 25.6% and 10.3%, respectively. Surgery carries acceptable risks for CTP-A and CTP-B cirrhotic patients; thus gastrectomy with D2 or more lymph node dissection can be safely carried out in CTP-A patients, whereas only D1 lymph node dissection is recommended in CTP-B patients. Radical gastrectomy is likely to be fatal in CTP-C patients, with mortality rates of 100% reported.

Oesophagectomy in cirrhosis patients carries a high risk of developing pulmonary complications (postoperative pneumonia, pleural effusions and chylothorax), ascites, anastomotic leaks during the first month, in addition to longer intensive care stays in comparison to patients without cirrhosis. Patients who are CTP-A have significantly lower mortality in comparison to CTP-B patients, and CTP-C disease remains a contraindication to oesophagectomy. MELD score >9 was associated with significantly lower 5-year survival and a score ≤9 was associated with similar outcomes to non-cirrhotic controls.

Bariatric surgery is considered safe to be undertaken in an experienced centre. A meta-analysis and systematic review concluded that postoperative and liver-related complications were higher among patients with cirrhosis when compared with non-cirrhotic individuals. Significantly lower postoperative complications were noted with sleeve gastrectomy compared with Roux-en-Y gastric bypass.

### Appendectomy

The lifetime risk of appendicitis is 8.6% in males and 6.7% in females, making it the most common surgical emergency worldwide. A meta-analysis showed that 30-day mortality for cirrhosis patients undergoing appendectomy was 9%, in comparison to 0.3% in those without cirrhosis. In patients with compensated cirrhosis, laparoscopic appendectomy is safer compared with an open approach. However, in many studies there was a lack of information on

Oesophagectomy in cirrhosis patients carries a high risk of developing pulmonary complications (postoperative pneumonia, pleural effusions and chylothorax), ascites, anastomotic leaks during the first month, in addition to longer intensive care stays in comparison to patients without cirrhosis. Patients who are CTP-A have significantly lower mortality in comparison to CTP-B patients, and CTP-C disease remains a contraindication to oesophagectomy. MELD score >9 was associated with significantly lower 5-year survival and a score ≤9 was associated with similar outcomes to non-cirrhotic controls. Bariatric surgery is considered safe to be undertaken in an experienced centre. A meta-analysis and systematic review concluded that postoperative and liver-related complications were higher among patients with cirrhosis when compared with non-cirrhotic individuals. Significantly lower postoperative complications were noted with sleeve gastrectomy compared with Roux-en-Y gastric bypass.
the severity of cirrhosis and other patient characteristics.73

Orthopaedic surgery
Adverse events are reported for cirrhosis patients undergoing total knee and hip arthroplasty but studies are mostly retrospective and limited.74–77 In a systematic review, cirrhotic patients are more likely to experience postoperative haemorrhage, surgical site infection and need for revision surgery after total hip arthroplasty.78 However, the severity of liver disease was not presented, and some studies report only short-term outcomes (table 2).

Interventions to mitigate the risk of surgery in patients with cirrhosis
A joint care approach is desirable to minimise the additional risk of surgery in patients with cirrhosis. The degree of portal hypertension can accurately predict postsurgical outcomes in cirrhosis. In the study by Reverter et al., patients with HVPG >16 mm Hg and ≥20 mm Hg were considered high and very high risk, respectively. Liver stiffness measurement of >25 kPa also correlates with CSPH and can be helpful in stratifying compensated cirrhosis.79 Endoscopy and contrast-enhanced CT scanning of the abdomen are indicated in all patients with cirrhosis. National guidance for endoscopic and pharmacological management of varices should be followed.80,81 Attention should also be given to optimising nutrition where possible.6 An area of debate is the role of portal decompression prior to surgery. Prophylactic TIPSS may facilitate planned surgery by reducing complications pertaining to portal hypertension. Uncontrolled retrospective studies suggest a potential role for TIPSS prior to surgery in selected patients (table 3). However, there is no evidence of improved surgical outcomes, and patient selection is not defined, although HVPG could be helpful as a guide. Moreover, the optimal timing of surgery after TIPSS is unclear and procedure-related complications should be considered. The present BSG guidance advises further research.81

<td>Lahat et al2018 Systematic review</td>
<td>19 studies—all retrospective</td>
<td>Planned surgery for: Gastrointestinal cancer in 38 (59%) patients, Benign digestive/pelvic surgery in 21 (33%) patients</td>
<td>TIPS successful in all patients, Encephalopathy—4.7% (controlled in all cases with treatment), All patients could be operated within a median delay of 30 days from TIPS (mortality rate: 8%) 1-year survival—80%</td>
</tr>
<tr>
<td>Fares et al2018 Retrospective study (2005–2013)</td>
<td>28 patients included Digestive (43%), Liver resections (25%), Abdominal wall surgery (21%) and Interventional Gastrointestinal endoscopy (11%)</td>
<td>Primary endpoint: Rate of failure (defined by inability to proceed to the planned intervention after TIPS placement or persistent decompensation 3 months after intervention), Secondary endpoints: Rate of complications, Parameters associated with failure, 1-year survival</td>
<td>Median time between TIPS and surgery—24 days, 1-year survival—70%, Procedure failure—6 (21%) patients (4/6 patients with HCC: two because of tumour progression before surgery), Persistent decompensation—2 patients, Hepatic surgery, history of encephalopathy and viral-related cirrhosis were associated with failure</td>
</tr>
<tr>
<td>Tabchouri et al2019 Retrospective study (2005–2016)</td>
<td>66 patients (compared with no TIPS group n=68)</td>
<td>Colorectal surgery performed in 54% patients, TIPS patients had higher CTP score, received more beta-blockers, 85% of patients in TIPS group underwent planned surgery</td>
<td>In TIPS group, 56 (85%) patients underwent planned surgery, Encephalopathy—15%, In TIPS and no-TIPS group, severe postoperative complications (18% vs 23%, p=0.392) and 90-day mortality (7.5% vs 7.8%, p=0.64) were similar</td>
</tr>
<tr>
<td>Goel et al2021 Retrospective study</td>
<td>Twenty-one patients undergoing prophylactic TIPS before non-hepatic surgery were identified.</td>
<td>Primary outcome: Discharged patients without hepatic decompensation after the planned surgery.</td>
<td>TIPS successful in all patients, 57% patients achieved primary outcome, Reduction in portal pressure gradient from 21.5 (11–35) to 16 (7–25) mm Hg (p=0.001), Post-TIPS complications in 7 (33%) patients with 4 patients experiencing encephalopathy, Post-TIPS portal pressure gradient was significantly higher in patients with adverse primary outcome, 1, 6 and 12 months survival was 90%, 80% and 76%, respectively</td>
</tr>
<tr>
<td>Chang et al2022 Retrospective study</td>
<td>In total, 926 patients (363 with cirrhosis undergoing surgery and 563 patients with TIPS) were included.</td>
<td>Propensity score matching (1:1) of preoperative TIPS (TIPS group) with patients without preoperative TIPS (no-TIPS group). Primary endpoint: Development of ACLF within 28 and 90 day after surgery, Secondary endpoint: 1-year mortality</td>
<td>Patient in no-TIPS group had higher rates of ACLF within 28 days (29% vs 9%; p=0.016) and 90 days (33% vs 13%; p=0.02) after surgery, 1-year mortality was also higher in the no-TIPS group (38% vs 18%; p=0.023) in comparison to TIPS group, Surgery without preoperative TIPS and CLIF-C AD score were independent predictors of mortality and ACLF development at 28 and 90 days, CLIF-C AD score &gt;45 was identified as a threshold for patients at risk of ACLF development in the postoperative period and will benefit from TIPS</td>

Areas requiring further study
1. Role of HVPG in stratifying risk prior to surgery, in patients with compensated cirrhosis or prior decompensation. Controlled studies are recommended.
2. Further multicentre prospective study on the utility of bespoke prognostic scoring systems. For patients with decompensated cirrhosis, these might include the EF-Chronic Liver Failure Acute Decompensation Score to guide risk.
3. In compensated cirrhosis, assessment of non-invasive markers of CSPH, such as liver stiffness measurements as a means of stratifying risk and selection for interventions prior to surgery.
4. The role of facilitative TIPSS prior to surgery. Further prospective comparative multicentre studies with a focus on patient selection criteria, for example, HVPG or liver stiffness measurements and postoperative outcomes.
5. Prospective studies to address the role of portal pressure lowering agents prior to surgery to reduce risk, including carvedilol, statins and combinations including rifaximin.
6. Prospective studies to investigate any potential role for prehabilitation within these cohorts of patients, which may improve surgical outcomes and reduce postoperative complications.
7. Further study to investigate the role of dynamic function testing such as viscoelastic tests and newer assays such as platelet function assays in predicting bleeding risk.
